

The QCD Black Disk Limit in Cosmic Ray Air Showers

H. J. Drescher

Johann Wolfgang Goethe University, Postfach 11 19 32, 60054 Frankfurt, Germany

We discuss particle production in the high energy limit of QCD. Due to a large gluon density, the interaction reaches the black disk limit and the projectile is resolved into its partonic structure at the saturation scale. This leads to suppression of forward particle production and hereby to a faster absorption of cosmic ray air showers. This property is most suitable for the distinction of evolution scenarios for the saturation scale, e.g. fixed and running coupling BFKL, the latter of which is favored by air shower measurements.

1. Introduction

The biggest uncertainty in air shower simulations is certainly the hadronic interaction model, since QCD is poorly understood at these high energies and accelerator data is not available.

Higher twist corrections become increasingly important at high energies. Attempts to account for this are the implementation of an energy-dependent p_t cutoff [1] for hard scattering or the resummation of enhanced pomeron diagrams in an efficient manner [2]. This way one tries to extend the applicability of hadronic interaction models up to GZK energies, $E \approx 10^{11}$ GeV.

Our approach [3] is to consider the black disk limit (or black body limit - BBL) at high gluon densities within the Color Glass Condensate (CGC) approach [4], where the interaction probability is close to unity. This leads to a suppression of forward particle scattering, the most important phase space region for cosmic ray air showers.

2. Hadron nucleus scattering at very high energies

The elastic and total scattering cross sections for quark-nucleus scattering may be written as follows [6]:

$$\sigma^{\text{el}} = \int d^2b [1 - \exp(-Q_s^2/4\pi\Lambda^2)]^2 \quad (1)$$

$$\sigma^{\text{tot}} = 2 \int d^2b [1 - \exp(-Q_s^2/4\pi\Lambda^2)] \quad (2)$$

If Q_s is large, the cross section approaches the geometrical limit.

Figure 1. Schematic view of the break-up of a hadron: the partonic structure is resolved at the saturation scale Q_s .

Here, two different evolution scenarios are considered for the saturation scale Q_s : fixed coupling

$$Q_s^2(x, A) = Q_0^2(A) \left(\frac{x_0}{x}\right)^\lambda, \quad (3)$$

and running coupling [5]

$$Q_s^2 = \Lambda^2 \exp(\log(Q_0^2/\Lambda^2) \sqrt{1 + 2c\alpha_s y}) \quad (4)$$

$$\alpha_s = \frac{b_0}{\log(Q^2/\Lambda^2)}, \quad (5)$$

with $y = \log(1/x)$. We assume $Q_0(A)$ to be proportional to the number of participants N_{part} . The constant c assures a smooth transition to the fixed coupling scenario at low y . At high energies $Q_s \approx 5$ GeV for running coupling and 20 GeV for fixed coupling for a central p-N collision [3].

Figure 2. Suppression of forward scattering for central p-N collisions.

The diagrammatic structure of an BBL event is schematically given in Fig. 1. The projectile interacts with the target as a whole and loses its coherence[7]. The partons are resolved at a scale given by the saturation momentum. An important feature is that soft physics is mostly suppressed, the typical transverse momentum being the resolution scale Q_s .

3. Monte Carlo implementation

Since the PDFs are resolved at the saturation scale Q_s , they provide the probability distribution for a parton to appear in the final state. The mean transverse momentum is approximately given by Q_s :

$$P_i(x) = f_i(Q_s^2(x), x) \quad (6)$$

$$\langle p_t \rangle \approx Q_s(x) \quad (7)$$

Note that Q_s is a function of x and b . For valence quarks we use the GRV94 parton distribution functions. For a baryon, first the three valence quarks are generated, then the remaining energy is used for gluon bremsstrahlung. Here we use the ansatz from Ref. [8]

$$xg(x, q_t^2) \sim \frac{1}{\alpha_s} \min(q_t^2, Q_s^2(x)) (1-x)^2, \quad (8)$$

Figure 3. Mean multiplicity of central p-N events.

which exhibits no divergence for low q_t . The produced gluons are ordered in rapidity and placed on strings between the valence quarks and the target nucleus, whose precise configuration is not important, since we are interested in forward scattering. In principle, a baryon-nucleus collision produces 3 strings, a meson-nucleus collision 2 strings. However, when the invariant mass between two of the three quarks is small, one cannot assume anymore that they fragment independently. Therefore, we implement a cut-off in invariant mass,

$$m_{\text{cut}} = m_\rho = 0.77 \text{ GeV} \quad (9)$$

below which two leading quarks are allowed to form a diquark. This is an important feature since it recovers the leading particle effect for low Q_s . The hadronization of the strings is done within the LUND model [9].

Of course, even at high energies, not all minimum bias events will be near the BBL. Therefore, we couple our model to a standard pQCD leading twist event generator, SIBYLL 2.1 [1]. Which of the two models is to be applied for a given impact parameter, follows from the condition

$$Q_s^{\text{Nucleus}}(x_F = 0.001) \gtrsim 1 \text{ GeV}. \quad (10)$$

The saturation momentum of the target at a longitudinal momentum fraction of $x = 0.001$ for the

Figure 4. Inelasticity as a function of energy.

projectile must be greater than a given value. The typical resolution scale for the valence quarks is correspondingly higher, since they have $x \approx 0.2$.

4. Results of the BBL event generator

Using the BBL as event generator, we can compare results in particle production to the pQCD model SIBYLL. At the same time, we compare the two different evolution scenarios, fixed and running coupling. Fig. 2 shows a Feynman- x distribution of charged particles for central proton-nitrogen collisions. One notices the absence of particle production in the very forward region, which is the typical property of this approach. This figure shows running coupling only; fixed coupling would be even more extreme. The absence of forward scattering is compensated by a relatively large multiplicity in the mid-rapidity region. In Fig. 3, we show the average multiplicities for fixed and running coupling BBL, as well as SIBYLL and QGSJET01 [11] results. Due to a missing ad-hoc p_t cutoff, QGSJET01 exhibits also a large multiplicity.

An interesting observable for air showers is the inelasticity,

$$K = 1 - \frac{E_{\max}}{E_0}, \quad (11)$$

where $E_{\max}$ is the energy of the most energetic

Figure 5. The fraction of BBL-events as a function of energy.

particle. A large value $K \approx 1$ means that most of the energy is used for particle production. A small value $K \approx 0$ is significant for elastic or diffractive events, where most of the energy remains in the leading particle. For air showers, a high inelasticity means that the shower are absorbed more rapidly in the atmosphere, giving rise to smaller $X_{\max}$ values. Fig. 4 shows how the suppression of the leading particle results in a higher K , especially for fixed coupling.

Finally, we show the fraction of BBL-events as a function of primary energy in Fig. 5. It reaches 90% at GZK energies. Note, that this does not mean that 90% of the cross section can be approximated as a black disk, since this also depends on the Q_s with which the event was created. But it gives some idea about how this phenomenon becomes more important at high energies.

5. Application of BBL to air showers

We implement the BBL event generator into the Seneca air shower code [10] and compute the mean $X_{\max}$ as a function of energy for proton primaries.

In Figure 6 we compare the predictions of SIBYLL 2.1 for proton and iron induced showers to the saturation model (BBL, for proton primaries only) with running and fixed coupling

Figure 6. $X_{\max}$ as a function of primary energy.

BFKL evolution of Q_s , respectively, and to preliminary Hires stereo data [12]. In the saturation limit, showers do not penetrate as deeply into the atmosphere. This is due to the “break-up” of the projectile’s coherence [7] together with the suppression of forward parton scattering (for central collisions). The comparison to the data might suggest a preferably light composition, but the uncertainties at these energies are still considerable.

6. Conclusions

We developed an hadronic interaction model considering the black disk limit in high density QCD. The suppression of forward scattering results in faster absorption of particles within air showers, which leads to a smaller $X_{\max}$. This feature allows one to distinguish between possible evolution scenarios for the saturation momentum.
